The interplay between crystallinity and superfluidity is of great fundamental and technological interest in condensed matter settings. In particular, electronic quantum liquid crystallinity arises in the non-Fermi liquid, pseudogap regime neighboring a cuprate's unconventional superconducting phase¹. While the techniques of ultracold atomic physics and quantum optics have enabled explorations of the strongly correlated, many-body physics inherent in, e.g., the Hubbard model², lacking has been the ability to create a quantum degenerate Fermi gas with interparticle interactions—such as the strong dipole-dipole interaction³—capable of inducing analogs to electronic quantum liquid crystals. We report the first quantum degenerate dipolar Fermi gas, the realization of which opens a new frontier for exploring strongly correlated physics and, in particular, the quantum melting of smectics in the pristine environment provided by the ultracold atomic physics setting⁴. A quantum degenerate Fermi gas of the most magnetic atom ¹⁶¹Dy is produced by laser cooling to 10 μK before sympathetically cooling with ultracold, bosonic ¹⁶²Dy. The temperature of the spin-polarized ¹⁶¹Dy is a factor $T/T_F = 0.2$ below the Fermi temperature $T_F = 300$ nK. The co-trapped ¹⁶²Dy concomitantly cools to approximately T_c for Bose-Einstein condensation, thus realizing a novel, nearly quantum degenerate dipolar Bose-Fermi gas mixture.

Quantum soft phases are states of quantum matter intermediate between canonical states of order and disorder, and may be considered the counterparts of liquid crystalline and glassy states in classical (soft) condensed matter physics. Such phases tend to arise under competition between short and long-range interactions and often result in the non-Fermi liquid, strongly correlated behavior manifest in some of the most interesting electronic materials of late: high- T_c cuprate superconductors, strontium ruthenates, 2D electron gases, and iron-based superconductors 5 . Recent theory suggests the long-range, anisotropic dipole-dipole interaction (DDI) among atoms in a degenerate Fermi gas, confined in an harmonic trap or optical lattice, may also induce transitions to states beyond the now-familiar insulating, metallic, and superfluid. Namely, phases that break rotational, translational, or point group symmetries may emerge in a manner akin to those found in classical liquid crystals,

e.g., the nematic and smectic¹.

Degenerate gases of highly magnetic fermionic atoms, such as ¹⁶¹Dy, may shed light on QLC physics without unwanted solid state material complexity, disorder, and dynamical lattice distortions. Uniaxial (meta-nematic)⁶ and biaxial nematic⁷ distortions of the Fermi surface of a harmonically trapped gas in the presence of a polarizing field may be observable as well as meta-nematic and smectic phases in 2D anisotropic optical lattices^{8–10}. An exciting prospect lies in the possibility of achieving spontaneous magnetization in dipolar systems coupled with nematic order^{11,12}. Additionally, DDI-induced pairing of fermions may lead to supersolidity¹³ and bond order solids¹⁴.

However, obtaining a quantum degenerate dipolar Fermi gas has been a difficult, unrealized experimental challenge. The highly magnetic fermionic atoms $^{53}{\rm Cr}$ (6 Bohr magnetons μ_B) and $^{167}{\rm Er}$ (7 μ_B) have yet to be cooled below 10 $\mu{\rm K}^{15,16}.$ The fermionic polar molecule $^{40}{\rm K}^{87}{\rm Rb}$ (0.57 Debye) has been cooled to near degeneracy $(T/T_F=1.4)^{17}$ and loaded into a long-lived lattice while partially polarized (0.2 D) 18 , but complexities arising from ultracold chemistry have hampered additional evaporative cooling $^{17}.$ In contrast, magnetic fermionic atoms do not undergo chemical reactions and are immune to inelastic dipolar collisions when spin polarized in high magnetic fields 19,20 .

The strong, r^{-3} character of the DDI arises in ground state polar molecules though a polarizing electric field that mixes opposite parity states. This electric field breaks rotational symmetry; consequently, observing the full range of true (non-meta) quantum nematic and fluctuating smectic phases, and their often unusual topological defects, is not possible in systems of fermionic polar molecules, especially in three dimensions. By contrast, highly magnetic atoms exhibit the DDI interaction even in the absence of a polarizing field. Moreover, the magnetic DDI can be tuned from positive to negative 21 , which may be important for simulating dense nuclear matter.

Dysprosium's isotopes 161 Dy and 163 Dy are the most magnetic fermionic atoms. With a dipole moment of $\mu=10~\mu_B,~^{161}$ Dy provides a DDI length $l_{\rm DDI}=\mu_0\mu^2m/4\pi\hbar^2$ that is factors of [400, 8, 2] larger than that of [40 K, 53 Cr, 167 Er]. With respect to fully saturated 40 K87Rb (0.57 D), 161 Dy is $30\times$ less dipolar for equal densities, but within a factor of 2 if confined in a lattice of less than half the periodicity. Lattices of wavelength 400–500 nm may be possible with Dy, whereas for molecules, photon scat-

Dy transitions and laser cooling and trapping scheme. a, Electronic energy level structure for bosonic 162 Dy (nuclear spin I=0) and fermionic 161 Dy (I=5/2), including laser cooling and trapping transitions. b, Additional ground and excited-state hyperfine structure exists for 161 Dy (F=I+J, where J=8 is the total electronic angular momentum and primes denote the excited states). Shown is the 32-MHz-wide transition at 412 nm used for the transverse cooling, Zeeman slower, capture MOT, and imaging beams. c, Blue-detuned, narrow-line (1.8 kHz-wide) MOT cooling transition at 741 nm. d, Spectra of 421-nm 162 Dy and 161 Dy (hyperfine) transitions including relative detunings of each MOT and Zeeman slower (ZS) laser. e, Transition and detuning spectra for MOT on 741-nm line. f, Sketch of dual species crossed optical dipole trap (ODT) aspect ratio along with magnetic field B and gravity g orientation. The imaging (421-nm) beam and the orthogonal ODT (1064-nm) beams are in the $\hat{\rho}$ -plane.

tering from rovibronic states at these wavelengths may reduce gas lifetimes. Indeed, $^{161}\mathrm{Dy}$ confined in a 450-nm lattice would provide a DDI strength more than $3\times$ larger than $^{40}\mathrm{K}^{87}\mathrm{Rb}$ confined in a 1064-nm lattice, if the electric dipole moment is unsaturated (0.2 D) to maintain collisional stability 18 . We estimate that the DDI strength of Dy confined in short-wavelength lattices would be sufficient to observe some of the exotic many-body physics recently proposed 13,14,22,23 .

Until recently, the laser cooling of Dy posed an insurmountable challenge due to its complex internal structure and the limited practicability of building repumping lasers: ~ 140 metastable states exist between the ground state and the broadest laser cooling transition at 421 nm (see Fig. 1a). Moreover, an open f-shell submerged underneath closed s-shells, combined with a large magnetic moment and electrostatic anisotropy from the L=6 orbital angular momentum, pose challenges to molecular coupled-channel calculations 24 which could otherwise guide early experiments. Even more daunting is the additional hyperfine structure of the fermions, shown in Fig. 1b–c, which splits each level into six.

Despite this vast energy level state-space, a repumper-

less magneto-optical (MOT) technique was able to individually laser cool and trap of all five high-abundance isotopes (three bosons, two fermions) to 1 mK using a single laser²⁵ (see Methods for details). Moreover, the complex homonuclear molecular potentials—involving 153 Born-Oppenheimer surfaces—and the associated multitude of scattering lengths did not inhibit the efficient Bose-condensation of spin-polarized ¹⁶⁴Dy through forced evaporative cooling¹⁹.

However, quantum degeneracy of identical Fermi gases is often more difficult to achieve than Bose-condensation because s-wave collisions are forbidden due to the requirement that the total wave function for two identical fermions be anti-symmetric with respect to particle exchange. Rethermalization from elastic collisions cease below the threshold for p-wave collisions (at typically 10–100 μ K), and efficient evaporative cooling can no longer be maintained. Co-trapping mixtures of particles—either as different spin states of the same atom or as mixtures of isotopes or elements—reintroduces s-wave collisions, providing a finite elastic cross-section for scattering even down to low temperatures. The mixture needs to be stable against inelastic collisions which could add heat or

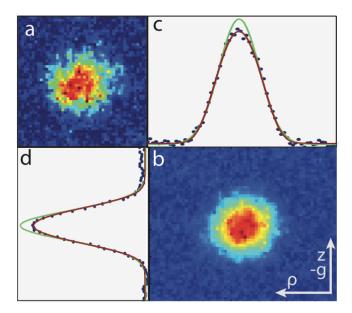

FIG. 2. Images of the Dy degenerate Fermi gas. a, Single shot time-of-flight absorption image at t=6 ms. b, Average of six images. Density integrations versus $\hat{\rho}$ (c) and \hat{z} (d). The green curve is a gaussian fit to the data's wings (radius $\sigma=20~\mu\mathrm{m}$), while the red curve is a fit to a Thomas-Fermi distribution. Data are consistent with a Thomas-Fermi distribution of $T/T_F=0.21(5)$. The Fermi velocity and temperature are 5.6(2) mm/s and 306(20) nK, respectively, and the gas temperature is 64(16) nK. The degenerate Fermi gas contains $6.0(6)\times10^3$ atoms at peak density $4(1)\times10^{13}$ cm⁻³.

induce trap loss. Evaporating $^{161}\mathrm{Dy}$ in a mixed state of two spins, as proved efficient for $^{40}\mathrm{K},^{26}$ would lead to large dipolar relaxation-induced heating even in the presence of small, mG-level fields because the inelastic, single spin-flip cross-section $\sigma_1 = \sigma \zeta(k_f/k_i)$ scales strongly with dipole moment 27 :

$$\sigma = \frac{8\pi}{15} F_1 F_2^2 \left(\frac{\mu_0 g_1 g_2 \mu_B^2 m}{4\pi \hbar^2} \right)^2 \frac{k_f}{k_i},$$

where F_1 is the spin of the atom whose spin flips $(F_1 = F_2)$ for identical particles), g_i are g-factors for atom i, m is mass, and k_i and k_f are the initial and final momenta. For ¹⁶¹Dy (¹⁶²Dy), F = 21/2 (F = J = 8) and $g_F (g_J) = 0.95$ (1.24). The function $\zeta(k_f/k_i) = [1 + \epsilon h(k_f/k_i)]$, where $\epsilon = \pm 1, 0$ and h(x) is defined in Methods, accounts for the contributions of even, odd, or all partial waves to the scattering process.

We choose, therefore, to seek a degenerate dipolar Fermi gas with Dy by sympathetically cooling 161 Dy with the boson 162 Dy while both are spin-polarized in their strong-magnetic-field seeking ground states: $|F,m_F\rangle=|21/2,-21/2\rangle$ for 161 Dy and $|J,m_J\rangle=|8,-8\rangle$ for 162 Dy. See Fig. 1a–c for energy level schemes. Preparation of this ultracold Bose-Fermi mixture—the first such mixture for strongly dipolar species—builds on our single-species technique 19 for Bose-condensing 164 Dy and relies

on the laser cooling and trapping of two isotopes before loading both into an optical dipole trap (ODT) for forced evaporative cooling. We sketch here the experimental procedure; further details are provided in the Methods.

Isotopes ¹⁶¹Dy and ¹⁶²Dy are collected sequentially in a repumperless MOT operating on the 421-nm transition²⁵ (Fig. 1d), with final MOT populations of $N=2\times 10^7$ and 4×10^7 , respectively. Next, simultaneous narrow-line, blue-detuned MOTs^{19,28} cool both isotopes to 10 μ K via the 741-nm transition (Fig. 1e) for 5 s to allow any remaining metastable atoms to decay to the ground state. The blue-detuned MOTs also serve to spin polarize^{19,28} both isotopes to their maximally high-field-seeking (metastable) states $m_F=+F$ ($m_J=+J$) for ¹⁶¹Dy (¹⁶²Dy).

The blue-detuned MOTs of the two isotopes can be spatially separated due to the dependence of the MOTs' positions on laser detuning^{19,28}. This allows the isotopes to be sequentially loaded into the 1064-nm ODT1 in Fig. 1f, which is aligned above the ¹⁶¹Dy MOT but below the ¹⁶²Dy MOT. First ¹⁶²Dy and then ¹⁶¹Dy is loaded into ODT1 by shifting the quadrupole center with a vertical bias field. All 741-nm light is extinguished before the spin of both isotopes are rotated via radiofrequency (RF) adiabatic rapid passage (ARP) into their absolute ground states $m_F = -F$ ($m_J = -J$) for ¹⁶¹Dy (¹⁶²Dy). The ODT1 populations of ¹⁶¹Dy and ¹⁶²Dy are both initially 1×10^6 before plain evaporation cools the gases to 1–2 μ K within 1 s. A 0.9 G field is applied close to the trap axis of symmetry \hat{z} throughout plain and forced evaporation. This provides a $\Delta m = 1$ Zeeman shift equivalent to 50 (70) μK for ¹⁶¹Dy (¹⁶²Dy). Because this is much larger than the temperatures of the gases, the field serves to maintain spin polarization while stabilizing the strongly dipolar ¹⁶²Dy Bose gas against collapse as its phase-space density increases¹⁹.

Magnetic Stern-Gerlach measurements and observations of fluorescence versus polarization are consistent with an RF ARP sequence that achieves a high degree of spin purity for each isotope. Remnant population in metastable Zeeman substates quickly decays to the absolute ground state via dipolar relaxation regardless of collision partner at a rate of $\Gamma \propto \sigma_1 n \bar{v} = 1 - 10 \text{ s}^{-1}$, where n is the atomic density and \bar{v} is the relative velocity during the plain evaporation stage. (Since $q_F F = q_I J$, collisions between Bose-Bose, Bose-Fermi, and Fermi-Fermi pairs result in Γ 's of similar magnitude as long as $k_i \approx k_f$ since $h(x\rightarrow 1)\rightarrow 0$. This condition is fulfilled during plain evaporation due to a low ratio of Zeeman-to-kinetic energy. For example, inelastic dipolar ¹⁶¹Dy-¹⁶¹Dy collisions ($\epsilon = -1$) proceed at rate $\Gamma = 1-5 \text{ s}^{-1}$ even in the absence of ¹⁶²Dy.) Thus, a (two-body) collisionally stable mixture of identical bosons and identical fermions is prepared within the 1 s between spin rotation and forced evaporation.

Subsequently crossing ODT1 with ODT2 forms an oblate trap with frequencies $[f_x, f_y, f_z] = [500, 580, 1800]$ Hz. Ramping down the optical power

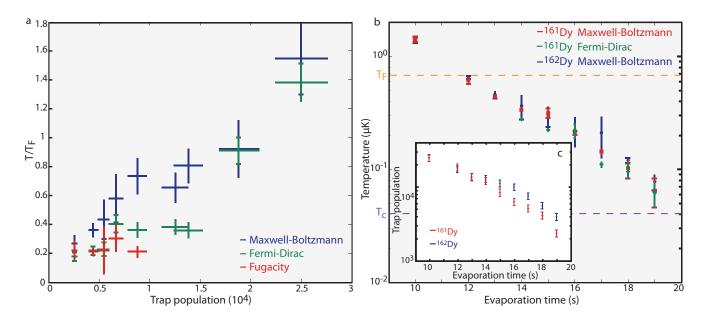

FIG. 3. Temperature and population of 161 Dy and 162 Dy mixture. a, Three measures (see text) of 161 Dy $\hat{\rho}$ temperature—to–Fermi temperature T_F as trap population decreases due to forced evaporation of the spin-polarized Bose-Fermi mixture. b, The dipolar Bose-Fermi mixture remains in thermal contact throughout the evaporation sequence as measured by fits of TOF densities to gaussian or TF distributions. The orange dashed line demarcates the boundary below which the temperature of 161 Dy is lower than T_F . Likewise, the purple dashed line demarcates the temperature below which T_c for 162 Dy Bose degeneracy would be reached given the trap frequencies and population at 19 s. c, Trap populations of the spin-polarized Bose-Fermi mixture versus evaporation time.

lowers the trap depth and evaporates spin-polarized $^{161}\mathrm{Dy}$ to quantum degeneracy; with a 19 s evaporation, the final trap has frequencies [180, 200, 720] Hz and $\bar{\omega}/2\pi$ is defined as their geometric mean. Figure 2 shows the density profile of ultracold $^{161}\mathrm{Dy}$, which is more consistent with a Thomas-Fermi (TF) distribution arising from Fermi-Dirac statistics than a gaussian arising from a classical, Maxwell-Boltzmann (MB) distribution.

Figure 3 shows a collection of such fits as a function of trap population and evaporation time. The T/T_F data are extracted from density profiles using three methods: 1) The high momentum wings are fit to a MB distribution with $k_BT_F=\hbar\bar{\omega}(6N)^{1/3}$ extracted from measured trap parameters and population (Fig. 3c); 2) similar to (1), but using a TF distribution; 3) fitting the fugacity to directly extract T/T_F . The last method is known to be inaccurate at higher temperatures, while the gaussian fit tends to overestimate the temperature below $T/T_F=1.26$ The evaporation does not yet seem to reach a plateau in cooling efficiency at 19 s; poor imaging signal-to-noise hampers measurements at longer evaporation times.

Data in Fig. 3b show that thermal equilibrium between the bosons and fermions is maintained throughout the evaporation, and Bose-condensation of 162 Dy within the mixture is nearly reached for an evaporation of 19 s. We estimate the corresponding critical temperature $T_c \approx 40$ nK of co-trapped 162 Dy by scaling the measured $T_c \approx 120$ nK of singly trapped 162 Dy with the cube root of their relative trap populations. (162 Dy has

been Bose-condensed in the absence of ¹⁶¹Dy; manuscript in preparation.) The nearly doubly degenerate dipolar Bose-Fermi mixture may lead to interesting dipolar and many-body physics once cooling efficiency improves.

While interacting BECs invert their anisotropic aspect ratio upon time-of-flight expansion, anisotropic degenerate Fermi gases tend to a spherical shape. As the DDI strength increases, the degenerate Fermi gas will expand into a prolate ellipsoid oriented along the magnetization direction regardless of trap aspect ratio. Furthermore, the gas may become unstable when the quantity $\epsilon_{dd} = \mu_0 \mu^2 (m^3 \bar{\omega}/16\pi^2 \hbar^5)^{1/2} > 1.^{29}$ At the lowest attained T/T_F , $\epsilon_{dd} = 0.2$ for ¹⁶¹Dy, and the ratio is l_{DDI}/l_F is 0.05. This DDI strength should lead to Fermi surface distortions (as yet unmeasured) at the percent level²⁹. Both ratios could be enhanced $\sim 3\times$ by increasing trap frequency using a more spherical confinement while maintaining stability of the dipolar Bose gas—and by increasing trap population. Additionally, the efficiency of evaporation—from gaussian fits to the data, $\gamma = 3 \frac{d(\ln T/T_F)}{d(\ln N)} \approx 2.3$ —may be improved by optimally tuning the magnetic bias field near one of the presumably large number of Feshbach resonances.

Surprisingly, we achieve the forced evaporative cooling of spin-polarized $^{161}\mathrm{Dy}$ without $^{162}\mathrm{Dy}$ to $T/T_F=0.7$ at $T_F=500$ nK. As mentioned above, achieving quantum degeneracy with spin-polarized identical fermions alone is usually not possible due to suppression of elastic scattering below the p-wave threshold 50 $\mu\mathrm{K}.^{24}$ That such a low

temperature ratio is achieved may be a novel consequence of the highly dipolar nature of this gas: namely, that a significant elastic cross-section persists to low temperatures due to the as yet unobserved phenomenon of universal dipolar scattering³⁰. The associated scattering rate is expected to scale as $m^{3/2}\mu^4$ regardless of the details of the short-range molecular potential. The predicted fermionic Dy universal dipolar cross-section, 7.2×10^{-12} cm², is nearly equal to ⁸⁷Rb's s-wave cross-section and could provide sufficient rethermalization for the evaporative cooling we observe. While future measurements will quantify spin purity, Fermi statistics does not inhibit identical fermions from spin purifying via dipolar relaxation once the RF ARP sequence populates the majority of the atoms in the absolute ground state. We will present these data along with supporting measurements of collisional cross-sections and scattering lengths in a future manuscript.

The efficacy of experimental proposals⁴ for studying the quantum melting of QLCs—important for better understanding the relationship of incipient electronic stripe order to unconventional superconductivity—may now be investigated using degenerate $^{161}\mathrm{Dy}$ in optical lattices wherein l_{DDI}/l_F can be greatly enhanced²². Looking beyond QLC physics, the large spin F=21/2 of the novel degenerate dipolar Fermi gas presented here opens avenues to explore exotic spinor physics as well as physics associated with strong spin-orbit coupling.

I. METHODS

Repumperless MOT. The 421-nm Zeeman slower laser is detuned -650 MHz from resonance, and a 421-nm MOT collects 2×10^7 $^{161}\mathrm{Dy}$ atoms in 4 s with the aid of a pre-slower transverse cooling stage. The MOT operates without repumpers despite many decay channels because the highly magnetic, metastable Dy remains trapped in the magnetic quadruple trap for a sufficiently long time to decay to the ground state²⁵. All beams derived from the 421-nm laser are then shifted down in frequency by 1.18 GHz and a $^{162}\mathrm{Dy}$ MOT collects 4×10^7 atoms in 100 ms. This scheme balances the need for preservation of $^{161}\mathrm{Dy}$ population against collisional decay²⁵ with the trapping of sufficient $^{162}\mathrm{Dy}$ for subsequent sympathetic cooling. Reversing this procedure results in fewer atoms due to heating of $^{162}\mathrm{Dy}$ in the magnetic trap by light scattered from the $^{161}\mathrm{Dy}$ Zeeman slower beam.

Narrow-line MOT. The narrow-line MOT lasers are bluedetuned 0.6 MHz from the 2-kHz wide 741-nm transition. The MOTs form below the quadrupole center such that the atomic transition is Zeeman-shifted to the blue of the laser. The MOT positions are determined by the balance of optical, magnetic, and grativational forces $^{19,28},$ and because the laser detunings for $^{161}\mathrm{Dy}$ and $^{162}\mathrm{Dy}$ can be adjusted independently, the two clouds can be easily separated.

ODT, RF ARP and crossed ODT. ODT1 has a waist of 30 (60) μ m and ODT2 has a waist of 20 (60) μ m in \hat{z} ($\hat{\rho}$). ODT1 is ramped on in 100 ms after 5 s of narrow-line cooling. After loading ODT1—120 (800) ms for 162 Dy (161 Dy)—a 4.3 G field is applied while a 20-ms RF sequence flips the spin of both isotopes to the absolute ground state. Dipolar relaxation further spin purifies the gas, and within the cross section σ_1 , $h(x) = -\frac{1}{2} - \frac{3}{8} \frac{(1-x^2)^2}{x(1+x^2)} \log \left(\frac{(1-x)^2}{(1+x)^2}\right)$ [see Ref.²⁷]). After spin purification, ODT2 is turned on, forming a crossed ODT with depth 300 μ K. ODT1 and ODT2 have initial powers of 18 W and 12 W. The background limited lifetime exceeds 180 s.

Forced evaporation scheme. The two beams of the crossed ODT are ramped down according to the functional form $P(t) = P_0/(1 + t/\tau)^{\beta}$ using experimentally determined parameters $\tau = 6$ s and $\beta = 1.5$ for both beams. Forced evaporation with ODT2 begins 5 s after ODT1. The beam powers are held at the final values for 400 ms after evaporation to allow for equilibration.

Temperature fitting. The TOF images are fit to both gaussian and TF profiles, the latter of the form²⁶

$$\left[\frac{A}{Li_2(-\zeta)}\right] Li_2\left(-\zeta e^{\frac{-(y-y_0)^2}{2\sigma_y^2}} e^{\frac{-(x-x_0)^2}{2\sigma_x^2}}\right) + c, \qquad (1)$$

with fitting parameters A, ζ , y_0 , x_0 , σ_y , σ_x , and c. The fitting is scaled by the constant $Li_2(-\zeta)$ such that parameter A corresponds exactly to the image peak OD. Because the high-velocity component of the cloud is less sensitive to signatures of quantum degeneracy, only the wings of the expanded cloud are used for the gaussian TOF fits. From the TF fits, the temperature is determined from size of the cloud, $\sigma^2_{TF,i} = (k_b T/m\omega_i^2)[1+(\omega_i t)^2]$, where ω_i is the trap frequency in \hat{z} or $\hat{\rho}$ and t is the expansion time. The cloud fugacity ζ is also determined by the TF fits and provides a direct measure of $T/T_F = [-6Li_3(-\zeta)]^{-1/3}$, where Li_3 is the third-order polylogarithm function.
